Context-Dependent Gene Regulation by Homeodomain Transcription Factor Complexes Revealed by Shape-Readout Deficient Proteins

Graphical Abstract

Highlights

- DNA shape readout by homeodomain TF complexes is revealed using SELEX-seq assays

- A shape readout-impaired homeodomain mutant destabilizes specific TF complexes

- This mutant was exploited to map TF complex composition and function genome wide

- The same mutation in an orthologous homeodomain is associated with a human disease

SUMMARY

Eukaryotic transcription factors (TFs) form complexes with various partner proteins to recognize their genomic target sites. Yet, how the DNA sequence determines which TF complex forms at any given site is poorly understood. Here, we demonstrate that high-throughput in vitro DNA binding assays coupled with unbiased computational analysis provide unprecedented insight into how different DNA sequences select distinct compositions and configurations of homeodomain TF complexes. Using inferred knowledge about minor groove width readout, we design targeted protein mutations that destabilize homeodomain binding both in vitro and in vivo in a complex-specific manner. By performing parallel systematic evolution of ligands by exponential enrichment sequencing (SELEX-seq), chromatin immunoprecipitation sequencing (ChIP-seq), RNA sequencing (RNA-seq), and Hi-C assays, we not only classify the majority of in vivo binding events in terms of complex composition but also infer complex-specific functions by perturbing the gene regulatory network controlled by a single complex.

INTRODUCTION

Gene regulatory networks are controlled by transcription factors (TFs) that target distinct gene sets by binding to specific DNA sequences. To determine which genes are regulated by a given TF, the genome-wide pattern of TF binding must be assayed and interpreted. The current standard approach is to profile in vivo TF occupancy using chromatin immunoprecipitation sequencing (ChIP-seq) or related methods (Cheetham et al., 2018; Johnson et al., 2007; Skene et al., 2018; Southall et al., 2013; Tosti et al., 2018). However, because these assays are blind to which cofactors a TF uses to bind any particular locus, it is difficult to infer how the DNA sequence determines the composition and configuration of TF complexes.

A complementary approach to identify TF binding sites involves probing the DNA binding specificity of TFs using high-throughput in vitro assays (Lambert et al., 2018). Binding preferences derived from such experiments are typically summarized by a position weight matrix (PWM) (Stormo, 2000). Despite their popularity, PWMs typically fail to explain a large fraction of in vivo TF binding events in higher eukaryotes (Wang et al., 2012). There are several possible explanations for this. First, low-affinity binding sites, which may not harbor a clear motif match, can be bound and functional in vivo (Crocker et al., 2016; Kribelbauer et al., 2019). Second, a TF may bind its genomic target sites cooperatively with other TFs (Jolma et al., 2015; Rodríguez-Martínez et al., 2017; Slattery et al., 2011; Spivak and Stormo, 2016; Stefflova et al., 2013) or with nucleosomes (Zhu et al., 2018). Third, indirect pull-down at highly accessible sites (ENCODE Project Consortium, 2012) or experimental artifacts (Baranello et al., 2016) may also contribute to our inability to fully explain TF binding in vivo.

Another approach to analyzing TF binding specificity is to obtain atomic-resolution structural information of protein-DNA complexes. To date, the structures of several thousands of protein-nucleic acid complexes have been determined (Berman et al., 2000), including representatives for all major TF families (Morgunova and Taipale, 2017). However, as with PWM models, the majority of these structures were obtained using only the DNA binding domain (DBD) bound to a single DNA ligand, and as a result, provide little structural insight into the range of binding modes exhibited by combinations of full-length TFs in vivo. Because DNA structure has been shown to play a role in TF-DNA recognition (Rohs et al., 2009), computational methods have been developed that allow high-throughput DNA structure prediction for a variety of features such as minor groove width (Chiu et al., 2020; Yang et al., 2014). In addition, several studies have found that TFs prefer specific DNA shape profiles that are not captured by canonical PWMs (Mathelier et al., 2016; Samee et al., 2019), suggesting that PWMs may miss these aspects of TF binding. However, because DNA shape is a consequence of DNA sequence, it is challenging to cleanly separate the contributions of DNA shape recognition from canonical base readout.
(i.e., a direct hydrogen bond) in TF binding. In one approach, structural information guided the design of mutant TFs that were impaired in shape readout, which were then used in high-throughput DNA binding experiments to assess the contribution of DNA shape to binding (Abe et al., 2015). Although the reverse—using DNA shape signatures derived from systematic evolution of ligands by exponential enrichment (SELEX) data to infer TF readout mechanisms in the absence of structural information—should in principle be feasible, there is to date no study that has systematically explored this approach.

Here, we show that without prior structural information high-throughput in vitro binding data and DNA shape signatures can be used to infer DNA shape readout mechanisms that are missed by canonical sequence motif analysis. In contrast to previous studies, we use this insight to design engineered TFs that can elucidate important principles underlying gene regulatory networks. By comparing the behavior of wild-type and engineered versions of the same TF in vivo, we obtain detailed information on TF complex-specific gene control and function. To illustrate this approach, we focused on a system of three interacting homeodomain (HD) transcription factors from *D. melanogaster*—one of the eight Hox proteins in complex with the homeodomain cofactors homothorax (Hth) and extradenticle (Exd). This trimeric TF system exhibits many of the complexities that exist for most eukaryotic TFs, including overlapping binding specificities within large TF families (Bürglin and Affolter, 2016; Merabet and Mann, 2016), the existence of multiple TF isoforms (Crist et al., 2011; Noro et al., 2006), cooperativity and latent DNA binding specificities (Slattery et al., 2011), and distinct biological functions that depend on different TF complex compositions (Moens and Sellier, 2006; Morata and Sánchez-Herrero, 1998; Noro et al., 2006; Yao et al., 1999).

We show that, as with Hox homeodomains (Abe et al., 2015; Joshi et al., 2007), basic amino acids within the N-terminal arms of both Hth and Exd homedomain select DNA sequences with minor groove width (MGW) minima. Thus, the Hox-Exd-Hth trimer prefers DNA sequences with a complex DNA shape that includes multiple optimally spaced MGW minima. We also find that the dependency on Exd’s ability to recognize its MGW minimum differs between Exd-containing complexes. We use this insight to design protein mutations that selectively reduce the stability of some, but not all, Exd complexes. Deploying this differential sensitivity as a tool in vivo, we classify each Exd binding site according to the specific homeodomain complex that it binds and infer complex-specific biological functions by linking distinct complexes to the set of target promoters they physically interact with. Finally, by combining information on 3D chromatin interactions with the variable dependency on DNA shape readout by Exd, we provide evidence that binding sites lacking a clear sequence motif are indirectly ChIPed as a consequence of interactions with sites bound in a sequence-specific manner.

**RESULTS**

**Hox, Hth, and Exd Form Complexes with Distinct Sequence and Conformation Preferences**

The TALE-family homeobox protein Exd can form a heterodimer with each of the eight *D. melanogaster* Hox factors (Slattery et al., 2011). Nuclear localization of Exd is dependent on Hth (Berthelsen et al., 1999; Rieckhof et al., 1997), a second TALE-family homeodomain TF that exists in two major isoforms (Noro et al., 2006): a full-length, homeodomain (HD) containing isoform, Hth FL; and a shorter, HD-less isoform, Hth HM (homothorax-Meis domain). Because the tight Exd-Hth protein-protein interaction occurs between the HM domain and Exd’s PBC domain (Ryoo et al., 1999) (Figure 1A), both isoforms are sufficient for the nuclear localization of Exd. In addition to acting as a Hox cofactor, Hth FL-Exd carries out Hox-independent functions such as patterning the proximal-distal axes of the appendages and specifying antennal identity (Abu-Shaar and Mann, 1998; Casares and Mann, 1998; Mann and Morata, 2000). As a result, a variety of Exd-containing complexes are present in vivo—Hth FL-Exd-Hox, with three HDs, Hth HM-Exd-Hox, or Hth FL-Exd, each with two HDs—as well as Hth FL binding as a monomer or homodimer without direct Exd-DNA contact (Figure 1B). Structural information, however, is largely limited to the HDs of heterodimeric Exd-Hox and homodimeric MEIS1 (the human ortholog of Hth) (Figure 1B). Thus, it remains unclear how the assembly of different complexes is promoted by the DNA sequence or how the combinatorial nature of homeodomain binding contributes to gene regulation.

To characterize in vitro binding preferences, we designed SELEX sequencing (SELEX-seq) libraries (Kribelbauer et al., 2017; Riley et al., 2014; Slattery et al., 2011) whose randomized region can accommodate the entire footprint of each respective complex (Figure 1C). Because inferring TF binding motifs of TF complexes with multiple potential configurations and flexible spacing is computationally challenging, we designed two libraries in which a fixed Hth binding site immediately precedes a 21-bp randomized region: (1) Lib-Hth-F, with an Hth site (TGA CAG) designated to bind Hth in forward orientation, and (2) Lib-Hth-R, with a reverse orientation (CTGT CA) (Figure 1C). We carried out SELEX-seq experiments for all individual complexes and constructed position-specific affinity matrices (PSAMs) and energy logos (Foat et al., 2006) based on the relative enrichment of oligomers of a given length (Figure 1C; STAR Methods). This analysis indicates that in the absence of Hox, Exd-Hth FL prefers to bind as a head-to-tail dimer analogous to Exd-Hox (Figure 1C). Introducing a Hox protein to the Hth FL-Exd complex results in the formation of a dominant Exd-Hox subcomplex, similar to when orientation-agnostic libraries are used (Figures S1A and S1B). Sequences suggestive of Exd-Hth FL (dark blue) and Hth FL-Hth FL dimer binding (dark pink) are also observed (Figure S1B).

**Relative Position and Orientation Preferences of a Ternary Protein-DNA Complex**

Characterizing the binding preferences of the ternary Hth FL-Exd-Hox complex requires taking into consideration both the orientation and position of the Hth FL binding site relative to the Exd-Hox heterodimer binding site. To infer this information from the SELEX-seq data, we first computed the relative enrichment of all DNA 12-mers both for Hth FL-Exd-Hox and Hth HM-Exd-Hox (Figures S1A and S1B). Using the PSAM for Exd-Hox to assign binding orientation, we find that in the absence of a Hth homeodomain, similar enrichments are observed for the forward ([Exd-Hox]F) and reverse ([Exd-Hox]R) orientations. However, when the

Figure 1. Probing the Diversity of Multi-homeodomain Complex Binding Using SELEX-Seq

(A) Schematic gene structures for three homeodomain TFs: homothorax (Hth; pink), extradenticle (Exd; green), Hox (Hox; blue). Arrows indicate protein interactions: PBC-domain (PBC); homothorax-Meis domain (HM); YPWM (Exd interaction motif).

(B) Existing 3D structures and schematic diagrams showing various possible complexes formed by Hth, Exd, and/or Hox. Arrows indicate Hth binding site (BS) orientation (forward, F = TGACAG and reverse, R = CTGTCA).

(C) SELEX-seq library design and derived sequence motifs (shown as energy logos). Arrows indicate protein binding site orientation with respect to the consensus NNAY homeodomain motif.

See also Figure S1.

homeodomain-containing isoform HthFL is used, the configuration [HthFL]2[Exd-Hox]e is preferred over [HthFL]2[Exd-Hox]e (Figures S1A–S1C).

Next, we estimated the contribution to the total binding free energy of complex binding associated with the “full configuration” (i.e., the relative position and orientation of the Hth and Exd-Hox subunits) by fitting a generalized linear model (GLM) that uses the intrinsic Exd-Hox binding affinity (for each 12-mer) and a configurational term simultaneously as predictors (see STAR Methods) (Figure 2A). For both fixed Hth binding site orientations (F and R), the configuration in which Hth binds on the Exd side of the Exd-Hox dimer was favored (top rows of estimates; Figure 2A). In addition, a preference for shorter spacers was observed for the Hth-F library compared to the Hth-R library (Figures 2A and S1D). This preference suggests that the N terminus of Hth’s HD faces Exd in Lib-Hth-R, shortening the distance between Hth’s HM and Exd’s PBC domains and thus allowing for a longer DNA spacer, while facing away in Lib-Hth-F, requiring the Exd-Hox subcomplex to be closer to the Hth binding site. The proposed structural configuration is consistent with the MEIS1 crystal structure (the human Hth ortholog; PDB: 4XRM) (Figure 2B) (Jolma et al., 2015).
To validate that the GLM-derived configurational free energy estimates recapitulate true differences in binding free energy, we performed competition electromobility shift assays (EMSAs) on binding sites with identical HthFL and Exd-Hox sequences (orientation = [HthFL]R[Exd-Hox]F), but different DNA spacer lengths. Two of the three tested spacers (3 bp and 7 bp) had similar predicted configurational energy in our model (blue and green curves in Figure S1E), whereas one (0 bp) was less

Figure 2. Dissecting DNA Minor Groove Width Readout by a Ternary Homeodomain Complex
(A) Systematic analysis of binding configurations of the ternary HthFL-Exd-Hox complex. SELEX probe counts after two rounds of affinity-based selection were analyzed using a generalized linear model that estimates the free energy associated with each configuration (i.e., the length of DNA spacer between the Hth and Exd-Hox sites, and their orientation with respect to each other) while accounting for the dependence on DNA sequence based on the enrichment of 12-mers observed for the simpler HthHM-Exd-Hox complex. Heatmaps show $\Delta \Delta G$ coefficients (in units of RT) for each particular configuration; red indicates stronger binding.
(B) Superposition of Meis1 (human ortholog of Hth; PDB: 4XRM) and Exd-Hox (PDB: 2R5Y) crystal structures onto B-DNA templates consisting of a Hth-F (TGACAG) or Hth-R (CTGTCA) binding site, followed by a 4-bp spacer (indicated by “ssss”) and an Exd-Hox site (2R5Y). Arrows indicate the relative positioning of the N-terminal domain of each HD (Hth, pink; Exd, green).
(C and D) Average minor groove width (MGW) profiles at increasingly stringent SELEX binding affinity cutoffs, for (C) HthFL-Exd-Hox (Lib-Hth-R) and three different spacer lengths (3–5 bp), (D) HthFL-Exd-Hox for a 4 bp spacer, contrasting all wild-type (top), shape-defective Exd (middle), or shape-defective Hth (bottom). Arrows indicate the position of N-terminal arm MGW readout, color saturation, and arrow size indicate the loss or gain of specific MGW minima respectively. See also Figures S1 and S2.
favorable for binding (red curve in Figure S1E). These experiments indeed confirm the predicted effect of spacer length variability on binding affinity.

**Optimal Binding by the Ternary HthFL-Exd-Hox Complex Relies on Minor Grove Shape Readout by All Three Homeodomains**

The currently available structures of homeodomain-DNA complexes suggest that the spacer DNA separating the HthFL and Exd-Hox binding sites is not directly contacted by any of these proteins. However, because DBDs were used rather than full-length proteins, the contacts observed in these structures may not capture all relevant contributions to complex assembly. To determine whether the sequence of the DNA spacer might contribute to the thermodynamic stability of the complex, we computed oligomer enrichment over the first four nucleotide positions downstream of the fixed Hth site in Lib-Hth-R, retaining only those probes that matched the 12-bp PSAM for Exd-Hox over positions 5–16. A preference for AT-rich sequences observed in the most highly enriched spacers (Figure S1F) suggested that the spacer may influence binding affinity via DNA minor-groove shape readout, which has been shown to play a critical role in DNA recognition for many TFs (Abe et al., 2015; Jolma et al., 2015; Rohs et al., 2009; Slattery et al., 2014; Zhou et al., 2015).

To analyze the relationship between spacer sequence preference and DNA shape readout, we fit a mechanism-agnostic generalized linear model (GLM) using base identities over the first 15 nucleotide positions of the variable region (3-bp spacer and a 12-bp Exd-Hox site) as predictors, while keeping the first two base pairs within the Exd-Hox site fixed (Figures S1G and S1H; see STAR Methods for details). Consistent with recent analyses (Rube et al., 2018), spacer preferences derived from a GLM that neglects dependencies between nucleotide positions agreed well with a GLM in which each spacer oligonucleotide was scored separately (R² = 0.81, Figure S1I). By taking subsets of sequences defined by an increasingly stringent cutoff of their GLM-based affinity and computing their average minor groove width (MGW) profile using pentamer tables (Zhou et al., 2013), we visualized the relationship between intrinsic DNA shape and probe selection in the SELEX-seq assay (Figures 2C and S1G). In addition to the two common MGW minima preferred by anterior Hox TFs (Abe et al., 2015; Joshi et al., 2007) (Figure 2C, blue arrows) we observed a strong preference for a narrow minor groove within the 3-bp spacer region separating the Hth and Exd-Hox binding sites. Notably, when we used the same approach to examine spacers longer than 3 bp, this broad MGW minimum split into two narrow ones that were adjacent to the Hth and Exd binding sites, respectively (Figure 2C, pink and green arrows).

These observations suggest that both Hth and Exd can take advantage of local narrowing of the DNA minor groove by inserting positively charged amino acid side chains from their N-terminal arms into the minor groove of the spacer (Figure 2C). To experimentally test this hypothesis, we made mutations in the positively charged amino acids within Hth’s and Exd’s N-terminal arm, similar to those designed previously for Hox proteins (Abe et al., 2015). For Hth, we mutated all 3 positively charged amino acids to alanine (HthK3A,K4A,R5A, which we will refer to as Hth-shape, Figures S2C and S2D), and for Exd, we chose the double arginine mutant with the strongest apparent impact on binding (Figures S2C and S2D, ExdR2A,R5A, which we will refer to as Exd-shape). Generating new SELEX data using the mutant proteins and repeating the analysis of Figure 2C for a spacer of 4 bp revealed that the mutant HthFL-Exd-Hox complex lost the ability to select sequences containing the corresponding MGW minimum (Figure 2D, translucent arrows). In addition, Exd-shape blunted one of the previously observed (Abe et al., 2015; Joshi et al., 2007; Slattery et al., 2011) preferences for a narrow minor groove by anterior Hox proteins, suggesting that shape-readout by Exd promotes Hox shape readout.

**The Stability of Exd-Containing Complexes Depends to Different Degrees on MGW Readout by Exd**

Given that ternary HthFL-Exd-Hox complex binding relies on MGW readout by Exd’s N-terminal arm, we tested whether this shape readout was required for all identified Exd-containing complexes: (1) Exd plus Hox-HthHM (the HD-less isoform of Hth), (2) Exd plus Hox-HthFL, and (3) Exd plus HthFL alone. When we compared sequence logos, all three ExdMT-containing complexes selected for a similar Exd half site with a shared optimal sequence (ATGAT; Figure 3, green shaded area). In contrast, the MGW readout profiles revealed large differences in the extent to which Exd selects for a narrow minor groove (Figure 3B, green shaded area): the strongest MGW minimum is selected by HthHM-Exd-Hox while there is hardly any selection for a MGW minimum by the Exd-HthFL complex.

These observations reveal that analyzing the sequence preferences of SELEX-seq experiments in terms of DNA shape features can uncover structural readout mechanisms that differ between TF complexes that are not revealed by standard PWMs. To verify the complex-specific differences in Exd MGW readout and to probe the extent to which they are relevant for complex stability, we performed SELEX and EMSA assays using several Exd N-terminal arm mutants (Figures 3B and S2A–S2D). Strikingly, two single substitutions within Exd’s N-terminal arm (ExdR2A and ExdR5A) were each sufficient to abrogate binding of the HthHM-Exd-Hox complex to the same extent as a key hydrogen bonded residue in the z3 recognition helix of Exd (ExdR51A) (for numbering of amino acids see Burglin and Affolter [2016]) (Figures 3C, red arrows in top panel, and S2A). By contrast, when the same R-to-A mutations in Exd were tested in the context of HthFL-Exd-Hox or Exd-HthFL, binding stability was only mildly affected (Figures 3C, S2C, and S2D). Moreover, for both HthFL-Exd-Hox and Exd-HthFL, the preference for Exd’s MGW minimum was no longer detectable in the SELEX-seq experiments using the Exd-shape mutant (Figure 3B, red shaded area), even though the optimal Exd half site was still preferred (TGAT) (Figure 3A, red shaded area). Together, these findings demonstrate that, first, although Exd’s N-terminal arm minor groove contacts are not visible in existing crystal structures (Figures 2B and S2E) and cannot be deduced by canonical motif analyses (Figure 3A), they can make large contributions to the binding free energy (Figure 3C). Second, the requirement for Exd’s MGW readout is complex-specific: the three HD HthFL-Exd-Hox and the two HD Exd-HthFL complexes can tolerate...
mutations in Exd’s N-terminal arm, while the two HD Hth\textsuperscript{HM}-Exd-Hox complexes cannot. Third, the dependency on MGW shape readout can be revealed by high-throughput binding data.

**Differential Sensitivity to Shape Readout Impairment Changes the Rank Order of Homeodomain Complex Binding**

To determine the extent to which the Exd shape-readout mutant differentially impacts complex formation, we systematically compared the sequences selected by the mix of Hth\textsuperscript{FL}-Exd-Hox with those selected by Hth\textsuperscript{FL}-Exd\textsuperscript{shape}-Hox complexes in our SELEX-seq experiments using the 21-bp libraries (Figures 4A and S3D). This analysis revealed a large variation in the extent to which binding to a particular DNA sequence is affected by the Exd\textsuperscript{shape} mutant. To interpret these observations, we used the PSAMs derived from the SELEX experiments on each complex individually (Figure 1C, i.e., the Exd-Hth\textsuperscript{FL} only library) to assign the bound complex for each DNA sequence (Figures 4A, colored points, S3D, and S3G). This analysis confirmed that, in addition to discriminating between Hth-Exd-Hox complexes containing either the Hth\textsuperscript{FL} or Hth\textsuperscript{HM} isoforms, Hox-containing complexes are more sensitive to this mutation than non-Hox-containing complexes (Figures 4A, S3D, and S3G). Binding of Hth\textsuperscript{FL} homodimers was not impacted, binding of Exd-Hth\textsuperscript{FL} heterodimers was slightly impaired, and binding of Hth\textsuperscript{FL}-Hox ternary complexes was affected the most. As a result, Exd-Hth\textsuperscript{FL} and Hth\textsuperscript{FL}-only sites, which are relatively low affinity in the wild-type dataset, emerged as the highest affinity sites in the Exd\textsuperscript{shape} dataset (Figures 4A and S3D).

Unexpectedly, this analysis also revealed a change in sequence selectivity for the trimeric HD complex containing Exd\textsuperscript{shape}: binding was less affected when the Y5 base-pair in the Exd-Hox heterodimer site (NTGAY\textsuperscript{Y}NAYNNN) was C-G instead of T-A (Figures 4A and S3D).
observed when SELEX-seq was performed with the Exd\textsuperscript{shape}-Hth\textsuperscript{FL} complex alone (Figures 3A, motif, and S3D), further supporting the notion that the interaction of Exd’s N-terminal arm with the minor groove differs depending on its binding partner. Notably, the T\textsubscript{C}+1 to C\textsubscript{G} transition is predicted to widen the minor groove at the position where the Hox spacer interacts with the DNA (Figure S3J). A smaller differential effect was observed at the N\textsubscript{C} position (N\textsubscript{C}TGAYNNAYNNN) (Figures S3A–S3C, S3E, S3F, and S3H), which can also be explained by a change in intrinsic MGW, yet is not specific to the Exd-Hox subcomplex (Figure S3I).

Taken together, these observations suggest that in parallel to optimized hydrogen-bonds with the ζ3 recognition helices, high-affinity binding sites for multi-protein TF complexes have an optimized DNA shape characterized by a set of MGW minima at specific positions. Losing the ability to interact with individual MGW minima affects the stability of some complexes more than others (Figure 4B).

**Homeodomain Complex Binding Behavior In Vitro Is Recapitulated In Vivo**

If in vivo occupancy is governed by the same binding rules and composition-dependent sequence preferences as in vitro, we might be able to explain more of the observed in vivo binding patterns by using mutant TFs tailored to lose binding free energy contributions from a specific minor groove interaction. To test this idea, we generated transgenic fly lines that ubiquitously express a V5-tagged version of Exd\textsuperscript{WT} or Exd\textsuperscript{shape} (Figure 4C; STAR Methods). Ubiquitous expression of Exd\textsuperscript{WT}-V5, but not Exd\textsuperscript{shape}-V5, fully rescued an exd null mutant, demonstrating that the two N-terminal-arm arginines are critical for viability (Figure S4A). Because the nuclear localization and therefore the activity of Exd depend on its interaction with Hth (Rieckhof et al., 1997), we confirmed that nuclear import of Exd\textsuperscript{shape}-V5 was not compromised (Figure S4B). To investigate whether lethality in Exd\textsuperscript{shape}-V5 is linked to a selective loss of distinct Exd-containing complexes, we carried out whole-genome ChIP-seq assays against the V5 tag of both Exd\textsuperscript{WT}-V5 and Exd\textsuperscript{shape}-V5 (in the presence of endogenous Exd) in wing imaginal discs (Figure 4D). We also used ChIP-seq to characterize the genome-wide binding patterns of Hth and the Hox protein Antp (STAR Methods), which is the dominant Hox protein expressed in wing discs. Visual inspection of the raw immunoprecipitation (IP) coverage tracks for Exd\textsuperscript{WT}-V5, Exd\textsuperscript{shape}-V5, Hth, and Antp at the Antp gene locus revealed that some Exd peaks are more sensitive to the Exd shape-readout mutation than others (Figure 4D). Strikingly, the binding signal loss (defined as the ratio of Exd\textsuperscript{WT}-V5 to Exd\textsuperscript{shape}-V5 coverage at each Exd\textsuperscript{WT} peak summit) correlated (r = 0.37, p < 2.2 x 10\textsuperscript{-16}) with predicted relative affinity for Hth\textsuperscript{FL}-Exd-Antp (Rastogi et al., 2018), despite the fact that multiple homeodomain complexes likely contribute to the overall Exd IP signal. This correlation confirms that selective MGW readout is also exploited in vivo. By contrast, assay for transposase-accessible chromatin sequencing (ATAC-seq) data from wing discs did not show an obvious correlation (Figure 4E).

We next focused on the subset of Exd\textsuperscript{WT}-V5 peaks that contain a match to the TGAYNNAY Exd-Hox consensus site (~20% or 752 peaks total). Recapitulating our in vitro findings, the 30% of these where occupancy is reduced is the most by the Exd\textsuperscript{shape} mutant are significantly more likely to have a high predicted affinity for Exd-Hox compared to the remaining 70% (p = 2.0 x 10\textsuperscript{-3}; t test; Figure S4C). At the same time, these peaks are significantly less likely to contain strong Hth-monomer sites (p = 3.6 x 10\textsuperscript{-7}; t test; Figure S4C), suggesting that Hth\textsuperscript{FL} can also stabilize Exd-Hox binding in vivo. Even more strikingly, when comparing between low-affinity Y5 = C and high-affinity Y5 = T for NTGAY\textsubscript{NN}AY binding sites, the altered sequence selectivity for Exd\textsuperscript{shape} identified in vitro was recapitulated in vivo, with Antp and Exd\textsuperscript{WT} preferring Y5 = T over Y5 = C sites, with the opposite binding preference observed for Exd\textsuperscript{shape} (p < 2.2 x 10\textsuperscript{-16} [Antp]; p = 0.01 [Exd\textsuperscript{WT}]; p = 8.2 x 10\textsuperscript{-04} [Exd\textsuperscript{shape}]; t test; Figure S4D). That the difference between these two classes is more pronounced for the Antp profile than for the Exd\textsuperscript{WT} profile suggests that while Exd-Hox binding is the dominant mode, Exd-Hth complexes might compete for these same sites in vivo (Figure S1A), potentially contributing to the overall Exd\textsuperscript{WT} IP signal and reducing the effect size.

**Identification of Complex Composition In Vivo on a Genome-wide Scale**

Given that the stability of each type of HD complex is impacted to a different degree by the Exd\textsuperscript{shape} mutation (Figures 3 and 3B), we reasoned that using the mutant binding loss as a diagnostic feature, along with relative affinities predicted from wild-type in vitro SELEX data, might allow us to categorize Exd\textsuperscript{WT} peaks (~3,700) in terms of a particular homeodomain complex (STAR Methods).

Using a combination of three ChIP enrichment values and three predicted binding affinity scores, each Exd peak was assigned to one of eight clusters (Figure 5A). Interpretable and distinct clusters were only obtained when ChIP coverage for both Exd\textsuperscript{shape}-V5 and Hox was included among the features (Figure S4E). Based on the average IP and binding site (BS) scores, we assigned each cluster to a particular type of complex and whether the BS was low or high affinity (Figure 5A). Importantly, the order of average Exd\textsuperscript{shape} binding loss per cluster closely recapitulated the one derived from our in vitro data in Figure 4B.

One cluster, comprising only 129 peaks, showed high mean values for all features, indicative of the ternary Hth\textsuperscript{FL}-Exd-Hox complex (Figure 5A). Having identified potential trimer sites in vivo, we tested whether the differences in spacer preference we observed in vitro (Figure 2A) could also be seen in vivo. To this end, we aligned all 129 trimer peaks by their highest-affinity Exd-Hox site, scored Hth\textsuperscript{FL} binding affinity in either orientation up- and downstream of that site, and averaged over a 4-bp moving window. Indeed, distinct spatial and orientation preferences were observed, which paralleled the in vitro trends (Figure 5B). As expected, an enhanced Hth-monomer binding affinity score was not observed for the 273 high-affinity Exd-Hox peaks (Figure 5B).

Interestingly, even though ATAC-seq signal intensity was not included as a feature in the clustering, it correlated with complex composition and configuration: sites where Exd directly contributes to DNA binding in a head-to-tail orientation (i.e., Hth\textsuperscript{HM}-Exd-Hox and Exd-Hth) were less accessible than sites that contain a
Figure 4. A Shape Readout Mutant Distinguishes between TF Complexes In Vitro and In Vivo

(A) Classification of 12-mer DNA sequences in terms of their observed in vitro relative enrichment (Lib-Hth-R) in the presence of Hth\textsuperscript{fl}, Hox, and either Exd\textsuperscript{WT} or Exd\textsuperscript{shape}. Points/sequences are colored according to which particular HD complex best explains their enrichment: Hth dimers (purple), Exd-Hth\textsuperscript{fl} (dark blue), or Hth\textsuperscript{fl}-Exd-Hox (low-affinity: \textit{Y5} = C, NTGACNNAYNNN, coral red; or high-affinity: \textit{Y5} = T, NTGATNNAYNNN, green).

(B) Schematic illustrating the context dependence of binding loss due to the Exd\textsuperscript{shape} mutation.

(C) To perform in vivo validation, transgenes carrying either Exd\textsuperscript{WT} or Exd\textsuperscript{shape} tagged with V5 were inserted into the attp40 landing site on chromosome II in the background of endogenous Exd.

(D) Tracks showing, at the Antp locus, the result of anti-V5 ChIP-seq experiments performed on third instar larval wing discs of flies homozygous for tub &gt; exd\textsuperscript{WT}-V5 (green) or tub &gt; exd\textsuperscript{shape}-V5 (red) transgenes and endogenous Exd. Hth (orange) and Hox (Antp; blue) ChIP-seq, as well as ATAC-seq (gray) tracks are also shown for reference. Background shading indicates peaks that are strongly lost (red), mostly unaffected (gray), or partially lost (yellow) by the Exd\textsuperscript{shape} mutation.

(E) Raw coverage tracks around the Exd\textsuperscript{WT}-V5 ChIP-seq peak summit for IP signals from Exd\textsuperscript{WT}-V5, Exd\textsuperscript{shape}-V5, Hox, and Hth, along with binding site (BS) affinity scores for Exd-Antp, and ATAC-seq signal. Peaks are ordered by the Exd\textsuperscript{WT}-V5 over Exd\textsuperscript{shape}-V5 IP-signal ratio (“Exd\textsuperscript{shape} binding loss”).

See also Figure S3.
Hth binding site bound independently of Exd (i.e., Hth-only and Hth\textsuperscript{FL}-Exd-Hox) (Figure 5A). This observation suggests that different TF-complexes or configurations might have opposing effects on DNA accessibility and gene expression. However, further studies will be required to rule out that tissue complexity and expression heterogeneity might contribute to the observed differences.

To estimate how many Exd peaks within each cluster of Figure 5A can be explained by one of the three distinct binding affinity models, (Exd-Antp, Exd-Hth, or Hth-monomer), we visualized the raw input features used in our unbiased clustering (Figure 5C). For 7 out of 8 clusters (comprising almost 80% of all peaks), we observed significant enrichment for at least one complex-specific sequence motif around the peak summit. Only a single cluster of peaks remained unclassified, which we refer to as motifless sites. This last cluster was also not enriched in any other sequence-specific motif when analyzed by the de novo motif discovery algorithm MEME-ChIP (STAR Methods) (Machanick and Bailey, 2011).

The Exd\textsuperscript{shape} Mutant Reveals Distinct Biological Functions for Different Complexes

Because the Exd\textsuperscript{shape} mutant predominantly impacts the binding of Exd-Hox complexes, we should in principle be able to identify the gene network directly controlled by Exd-Hox. To circumvent the lethality caused by the Exd\textsuperscript{shape} mutation, we tagged the endogenous Exd C-terminally with GFP (Exd-GFP) and used the deGradFP method to deplete endogenous Exd\textsuperscript{GFP} protein (Caussinus and Affolter, 2016) (Figures 6A and S5A). After expressing the deGradFP system for 24 h, we performed RNA sequencing (RNA-seq) on third instar imaginal wing discs of male flies that carried either a copy of tub > exd\textsuperscript{WT} or of tub > exd\textsuperscript{shape} (Figure 6A). At a false discovery rate of 5%, we detected 392 genes upregulated in Exd\textsuperscript{shape} relative to Exd\textsuperscript{WT}, and 322 downregulated genes (Figure 6B). Among the former were exd and hth, which showed mild upregulation suggestive of an autoregulatory feedback loop for Exd-containing complexes.

See also Figure S4.

Figure 5. Attribution of Binding Complex Composition In Vivo Using the Exd\textsuperscript{shape} Mutant

(A) Classification of all Exd\textsuperscript{WT}-V5 peaks based on ChIP-seq enrichment for Exd\textsuperscript{WT}-V5, GFP-Antp, and Exd\textsuperscript{shape}-V5 and predicted binding site affinity for Exd-Antp, Hth-monomer, and Exd-Hth. The heatmap shows average Z-scores across all six input features for each cluster. Average Z scores for Exd\textsuperscript{shape} binding loss and ATAC-seq signal (the latter not used for the clustering) are shown using orange-green and yellow-black color scales, respectively. The number of peaks per cluster and the assigned complex are indicated on the left.

(B) Comparison of length preferences for the spacer between the Exd-Hox and Hth binding sites between in vitro and in vivo context. Estimated binding free energy for all four possible Hth configurations centered around the [Exd-Hox] site derived from SELEX data is shown in the top panel (red-black color scheme). The middle and bottom panel indicate the 4-bp moving average binding site score for Hth centered around the highest-scoring Exd-Hox site for either the 129 trimer (middle) or 273 high-affinity Exd-Hox cases (bottom).

(C) Raw tracks for IP coverage and binding affinity centered around each peak summit for all six input features, along with the ATAC-seq signal. The deduced identity of the bound complex for each cluster is indicated on the left and affinities are shown on the right.

See also Figure S4.
Figure 6. Using Exd-shape to Perturb Complex-Specific Gene Networks

(A) Using the Exd-shape mutation as a genetic tool to dissect the gene expression response of Exd-Hox binding loss in vivo. CRISPR-Cas9 based tagging of the endogenous Exd locus with GFP allows time-controlled removal of endogenous Exd protein using the deGradFP system in the background of either tub > exdWT-V5 or tub > exd-shape-V5 transgenes.

(B) Volcano plot of the false discovery rate (FDR) versus the log2-expression-fold change in Exd-shape compared to ExdWT (reference) is shown. Genes upregulated in Exd-shape are shown in green; downregulated genes in red.

(C) Using Hi-C data to assign peaks to the promoter they contact the most. Shown is a region on chromosome 2L encompassing the mid gene locus. ExdWT-V5 IP coverage track is shown above the Hi-C map at 5-kbp resolution. Promoter regions (orange) and different HD complex types are shown as colored boxes. Arrows indicate examples of contacts in 3D space between enhancers (peaks) and promoters.

(legend continued on next page)
To map individual TF peaks to their gene promoters and identify direct targets, we generated in situ chromatin capture (Hi-C) data from wing discs (Monahan et al., 2019; Rao et al., 2014) (Figures S6C and S6E) and asked whether the cumulative contact frequency between Exd peaks and a gene promoter (within 50 kilobase pairs [kb]) might be a predictor for how the expression of a given gene responds to the Exd\textsuperscript{shape} mutation. Indeed, we observed a positive correlation between cumulative peak-promoter contact frequency and expression log-fold-change for all upregulated genes (Pearson correlation $r = 0.13$; $p = 9.4 \times 10^{-13}$) (Figure 6D). Among downregulated genes, the same correlation was not significant ($r = 0.03$; $p = 0.11$). Upregulated, but not downregulated, genes also had significantly more contacts with the motif-dependent Exd peaks, regardless of complex composition (Figure S5B), suggesting that many target gene promoters may be contacted by both Hox-containing and Hox-free Exd peaks. Similar to what has been reported for Hox proteins, Exd-containing complexes might recognize their in vivo target sites by forming 3D local microenvironments with high TF concentrations, also referred to as “transcriptional hubs” (Alberti et al., 2019; Furlong and Levine, 2018; Tsai et al., 2017). Such larger molecular assemblies that can contain multiple peaks would explain the apparent overlap in regulatory networks among different Exd-containing complexes. To explore this hypothesis, we generated Hi-C maps of third-instar imaginal wing discs at 5-kbp resolution (Durand et al., 2016) (Figure 6E; STAR Methods). Chromatin interaction frequencies for all pairs of Exd peaks extracted from these data revealed a surprising level of structure (Figure 6E). Indeed, Hi-C bins that contained Exd peaks were significantly more likely to contact each other than those containing randomly sampled and size-matched reference sets of ATAC-seq peaks ($p = 4.9 \times 10^{-34}$), even when the set of binned peak interactions is limited to non-duplicated genomic bins ($p = 2.6 \times 10^{-35}$) (Figure S6A; STAR Methods). This substructure in Exd-peak-derived Hi-C maps is also retained when normalizing for expected local contact frequencies using the method of (Rao et al., 2014) (Figure S6A, insets). Together, these analyses suggest that Exd-containing chromatin-bound complexes co-localize within pre-defined contact domains significantly more often than expected by chance. A prominent example of this behavior is found on chromosome 2L, where many Exd peaks cluster within an area of ~200 kbp (Figure 6E), containing genes such as no ocelli and elbow B, which are involved in eye-antenna development (Lueque and Milán, 2007), and genes related to neuronal function such as puckpocket (an ion channel) and Partner of Bursicon, part of the Bursicon neurohormone dimer (Luo et al., 2005).

Despite the apparent lack of a clean spatial separation between different Exd-containing complexes and the resulting overlap of the respective gene regulatory networks they control (Figure 6E), we reasoned that because Exd-Hox binding is most strongly affected by the Exd\textsuperscript{shape} mutation, changes in gene expression should be driven by the loss of this particular complex. To test this, we used our Hi-C data to identify the most frequently contacted promoter for each peak. Analyzing Gene Ontology (GO) associations showed that the genes directly contacted by Exd-Hox peaks are indeed enriched for several distinct functions that are missed when no discrimination is made among the various Exd-containing complexes (Figure 7). Among those functions were several neuronal categories, such as axon guidance, chemotaxis, and cell projection/cell morphology related ones. Accordingly, the same GO categories scored significantly when taking the overlap between upregulated genes in Exd\textsuperscript{shape} and genes more highly expressed in the wild-type central nervous system (CNS) compared to wild-type wing discs (Figure 7). As expected, no enrichment for particular GO categories was observed for non-Hox Exd-Hth\textsuperscript{FL} peaks, suggesting that they predominantly occur as a byproduct of overlapping gene networks. Only when the subset of genes contacted by both an Exd peak classified as “Hth-only” and one classified as “Exd-Hox” was considered, categories related to biosynthesis and metabolism emerged as enriched (Figure 7).

Surprisingly, when analyzing the gene set contacted by motifless Exd peaks we found the same functions enriched as when all Exd peaks were used without distinction (Figure 7). Taking a closer look at the raw ChIP-seq signals at motifless peaks, we found that they nevertheless displayed a wide variation in Exd\textsuperscript{shape} IP signal loss (Figure S6B), suggesting that the degree to which they are occupied by Exd might be driven by a particular Exd-containing complex, and thus depend on MGW readout to different degrees (Figure S6B). Given the high degree of spatial association among Exd-containing peaks genome-wide, we speculated that the similarity in GO category enrichment of “motifless” and “all Exd” target genes (Figure 7), as well as the variable Exd\textsuperscript{shape} IP signal loss, might be a consequence of motifless sites being crosslinked to those containing a motif, perhaps as part of a nuclear hub. Supporting this notion, the IP signal loss at motifless Exd sites correlates with that at motif-dependent sites they are in contact with (Figure S6C). This correlation was improved when more than just the most contacted motif-containing peak was used in the analysis (Figure S6C). Importantly, a correlation of Exd\textsuperscript{shape} IP signal loss between randomly assigned pairs of motifless and motif-dependent peaks was not detected (Figure S6D). Together, these data are consistent with the idea that motifless sites are ChIPed because they are in close proximity to and crosslinked with motif-containing sites as part of larger molecular assemblies of Exd-containing complexes. Why and how they are recruited in the absence of a clear sequence signature should be of interest for future studies.

(D) Cumulative promoter to Exd-peak contact frequency is significantly correlated with expression log$_2$-fold-change for upregulated (green), but not downregulated genes (red).

(E) Hi-C contact maps of wild-type (including tub > exd\textsuperscript{WT-V5} transgene) wing discs for chromosome 2L showing either all chromatin contacts (left; binned at 25 kb resolution), a selection based on the set of all Exd peaks (middle; binned at 5 kb resolution), or one based on a size-matched random sample of ATAC-seq peaks (right; binned at 5 kb resolution). Color bars above and next to each plot show the type of chromatin bin. The gene structure and raw Exd\textsuperscript{WT} IP signal of the highlighted area on the Hi-C maps (yellow box) is shown below. See also Figures S5 and S6.
DISCUSSION

Accurate prediction of which DNA sequences a given TF or TF complex will bind in vivo is a hard and still unsolved problem, despite the availability of many complementary high-throughput datasets. A major reason why we fall short of this goal is that any one TF can bind a wide variety of DNA sequences with different partners. Thus, the assumption that a single binding mode captures the full range of binding behaviors in vivo is likely to be an oversimplification.

In this study, we showcase how insights into this problem can be obtained by inferring structural features of multi-TF complexes from high-throughput in vitro binding data and then using this information to perturb the system in a complex-specific manner. Importantly, the mechanistic insights we obtain challenge several currently held views on the nature of TF binding, including the subordinate role that structurally ill-defined protein regions and DNA sequences lacking readily defined motifs play in TF binding site recognition and stability. Our biophysically motivated analysis of SELEX-seq data revealed that both Hth and Exd rely on DNA shape readout when they bind with other homeodomain TFs. The reliance on DNA shape recognition by Exd’s N-terminal arm in some, but not all, Exd-containing complexes is reminiscent of latent sequence specificity, where Hox proteins gain specificity when they dimerize with Exd (Slattery et al., 2011). In the observations described here, latent shape readout occurs when Exd binds with Hox but not with HthFL. Thus, in contrast to studies that use shape features to improve the prediction of genomic binding patterns (Mathelier et al., 2016; Samee et al., 2019), our approach provides insight into structural readout mechanisms that can be leveraged to design TFs with predictable binding properties—here, a TF that selectively destabilizes a particular complex both in vitro and in vivo.

Because quantitative information about any readout mechanism that contributes to DNA sequence specificity is captured in high-throughput binding assays, it is likely that this approach can be used to infer structural mechanisms and molecular configurations for other TF systems as well. As illustrated by our analysis of different Exd-containing complexes, it is possible to demonstrate causality by comparing differences in shape profiles across TF binding partners even in the absence of mutant TF data (Figure 3B). Naturally occurring amino acid variations among closely related paralogs may represent another way to delineate sequence and shape readout from high-throughput binding data.

Our insight that a part of a TF that samples many configurations can differentially affect the assembly of distinct TF complexes in vitro ultimately allowed us to infer the bound complex for ~80% of all Exd ChIP-seq peaks, a significant improvement over what can typically be achieved using just a single motif. According to the current literature, the remaining 20% of sites, which lack a clear binding motif but display high accessibility, would likely be considered an artifact of ChIP-seq experiments (Baranello et al., 2016; ENCODE Project Consortium, 2012). However, the observation that the loss of ChIP-seq signal in the Exd^shape mutant at motifless sites parallels the loss at motif-dependent sites suggests that, at least for Exd, motifless sites do not occur independently of sequence-specific binding.

but may inherit their binding loss through direct interaction with other sites. Although we do not know the mechanism by which motifless sites are recruited, we speculate that intrinsic DNA properties such as increased negative electrostatic potential, DNA bending capacity, or the ability to keep regions free of nucleosomes might contribute to this phenomenon—aspects that might generally apply to TF binding in vivo.

Because the Exd*shape* mutant selectively perturbs Exd-Hox gene targets, we were able to reveal complex-specific functions that are missed when all Exd peaks are analyzed (Figure 7). For Exd-Hox, we found a repressive role that appears to limit the expression of genes that are normally active in the nervous system. This finding may provide an explanation for previous observations showing that although the Hox gene Antp is dispensable for wing formation, removing its activity often results in morphological abnormalities (Struhl, 1982). We also identified a common gene set controlled by Exd-Antp and Hth-only complexes—genes associated with metabolic function and biosynthesis. This finding may be relevant to the further investigation of the seemingly contradicting roles that Hox proteins and their cofactors play in the onset of cancer (Jia et al., 2018).

Notably, the latent shape readout mechanism defined here for Exd also appears to be relevant in vertebrates. The human genome encodes four highly conserved orthologs of Exd, namely Pbx1-4 (Merabet and Mann, 2016). In the mouse, where knockouts have been studied, all four pbx genes are essential for viability (Hisao et al., 2004; Machon et al., 2015; Moens and Selleri, 2006; Stankunas et al., 2008). Consequently, a complete loss-of-function (null) allele of p bx would be unlikely to contribute to human disease unless the gene was haplo-insufficient for a specific function. In contrast, a subtler perturbation of Pbx activity, analogous to the shape-defective mutation of Exd described here, could in principle contribute to human disease by interfering with the binding of specific Pbx-containing TF complexes. With this in mind, we examined several human genetics databases. Notably, missense mutations in Pbx1-3 homeodomains are underrepresented in healthy populations (https://gnomad.broadinstitute.org) (Lek et al., 2016), consistent with the essential function of these DBDs. An interesting exception is de novo mutations of N-terminal arm arginines of Pbx1 that are present in several patients diagnosed with congenital anomalies of the kidney and urinary tract syndrome (CAKUTHED) (https://www.omim.org/) (Heidet et al., 2017; Slavotinek et al., 2017): three patients had a mutation in either the R2 (1x) or R3 (2x) arginines of the Pbx1 homeodomain, equivalent to the ones mutated here in Exd. These Pbx1 mutants were also defective in their ability to activate a reporter gene harboring a perfect Exd-Hth binding site (Slavotinek et al., 2017). We speculate that these human p bx1 alleles are essentially DNA shape readout-defective mutants of Pbx1 and, as a result, are compromised in the binding of a particular subset of Pbx1-containing TF complexes to their respective binding sites, resulting in the highly specific CAKUTHED syndrome.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- **KEY RESOURCES TABLE**
- **LEAD CONTACT AND MATERIALS AVAILABILITY**
- **EXPERIMENTAL MODEL AND SUBJECT DETAILS**
  - Bacteria Growth Conditions
  - Fly husbandry
- **METHOD DETAILS**
  - Protein purification and mutagenesis
  - Binding and competition assays
  - SELEX Library Design
  - SELEX experiments
  - Sequencing and data processing
  - Computational analysis of complex configuration
  - Feature-based modeling using GLM
  - Affinity-shape correlation
  - Structural interpretation
  - Generation of transgenic and CRISPR-Cas9 fly lines
  - Immunohistochemistry
  - ChIP-seq
  - ATAC-seq
  - In situ Hi-C
  - RNA-seq

LEAD CONTACT AND MATERIALS AVAILABILITY

Further information and request for resources and reagents should be directed to the Lead Contact, Richard S. Mann (rsm10@columbia.edu). All fly lines and protein plasmids generated in this study are available from the Lead Contact without restrictions.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

**Bacteria Growth Conditions**

For recombinant protein purification BL21 (DE3) competent cells were inoculated and grown for 2 hours at 37°C before IPTG induction. Cells were harvested 4-5 hours after induction.

All electromobility shift assays (EMSAs) were performed using 2 nM radiolabeled DNA and protein concentration between 75-900 nM. Purified proteins were incubated for at least 30 min prior to loading in binding buffer (final concentration: 2% Glycerol, 30 μg/μl polydIdC, 40 mM NaCl, 40 mM Tris pH = 8.0, 0.4 mM MgCl2, 1mM DTT, 0.5 mM EDTA). After loading onto a 5% TBE gel, gels were run at 4°C for 2h in 0.5x Tris-running buffer.

**Fly husbandry**

For ChIP-seq, ATAC-seq and Hi-C experiments, transgenic or wild-type fly lines were kept at 25°C on molasses fly food. For deGradGP RNA-seq experiments, flies were raised at 18°C and shifted to 29°C for 24 hours before wing disc dissection.

**METHOD DETAILS**

**Protein purification and mutagenesis**

Fly proteins were obtained and purified as described in Slattery et al. (2011). Briefly, PET-expression vectors containing coding regions for full-length hth (Uniprot-ID: O46339), exd (Uniprot-ID: P40427), dfd (Uniprot-ID: P07548) and Hth HM-domain (amino acids 1-242; (Uniprot-ID: O46339) with hexa-histidine tags (except for Exd, which was co-purified with full-length Hth or HM-domain-only Hth) were transformed into Bl21 cells. Cells were grown for 5-7 hours, lysed, and proteins extracted with affinity purification using Cobalt-Talon beads (Clontech). Site-directed mutagenesis for Exd and Hth was performed by amplifying the original plasmid with primers harboring single amino acid replacements (arginine to alanine) using Taq-polymerase (NEB). Double and triple mutations were generated sequentially. See Key Resources Table for all generated mutations.

**Binding and competition assays**

Protein concentrations in Electromobility shift assays (EMSAs) were as follows: Dfd was kept constant at 150 nM; wild-type HthFL-Exd and HthHM-Exd was used at 100 nM; mutant proteins were increased from 75 nM to 300 nM (two lanes) or up to 900 nM (three lanes) (Figures 3C and S2A–S2D). For competition assays, a radio-labeled probe was competed out with increasing concentrations of unlabeled competitor DNA while keeping protein concentrations constant (100 nM). Dose-response curves and IC50 values were obtained using the R package drc. Spacers with zero, three and seven bases between the Hth and Exd-Dfd sites were tested (see Key Resources Table).

**SELEX Library Design**

The Lib-16 library contained a 16-mer random flank without fixed binding sites and data for HthHM-Exd-Dfd were taken from Slattery et al. (2011). The data for the HthFL-Exd SELEX-experiment were generated using a Lib-16 library as well, but following the design described in Kribelbauer et al. (2017). The Lib-Hth-F and Lib-Hth-R libraries contained a fixed Hth site –TGACAG in forward (F) and CTGTCA in reverse (R) orientation – immediately followed by a 21-bp random region. Library Lib-30 had a 30-bp random region and no fixed binding sites. Full library sequences are listed in (Key Resources Table). Libraries of different length and with fixed Hth binding sites were designed to facilitate the inference of binding models for TF complexes with variable configurations and large DNA footprints (> 12bp). The high complexity of the 30-mer library, where all complexes can form freely, prevents direct analysis of shape preferences for individual complexes due to insufficient counts per complex composition and complex configuration.
SELEX experiments
For Lib-Hth-F, Lib-Hth-R, and Lib-30, SELEX experiments were carried out using wild-type or mutant homeodomain proteins following the experimental procedures described in Riley et al. (2014) and Slattery et al. (2011). In brief, TFs were incubated with SELEX libraries and loaded onto EMSA gels. The TF-bound fraction was isolated from the gel, amplified and either subjected to another round of enrichment or prepared for sequencing. Two rounds of enrichment were performed for each set of experiments. For the HthFL-Exd and HthFL-Exd-Dfd SELEX-experiments using Lib-16, a single round of selection was performed using the library design described in Kribelbauer et al. (2017) (see Key Resources Table for library sequence). Data for HthHM-Exd-Hox were obtained from a previous study (Slattery et al., 2011). For each experiment, proteins of a final concentration of ~50 nM were assembled and incubated with excess DNA (10-20 fold) for 30 minutes. After each round of selection, the DNA was extracted from the gel amplified by either using Illumina’s small RNA primer sets or the set of primers described in Kribelbauer et al. (2017). Sequencing barcodes were added in a five cycle PCR step and the final library was gel-purified using a native TBE-gel before sequencing.

Sequencing and data processing
Libraries for HthFL-Exd and HthFL-Exd-Dfd (Lib-16) were sequenced using a v2 75-cycle high-output kit on an Illumina NEXTAGenome Center at Columbia University. Libraries Lib-Hth-F and Lib-Hth-R with either Hth or Exd shape-readout mutant in complex with the respective other wild-type protein and Dfd, as well as the Lib-30 HthFL-Exd-Dfd experiment were all sequenced at the New York Genome Center using separate lanes on an Illumina HiSeq 2000 sequencing machine. Libraries Lib-Hth-F and Lib-Hth-R with wild-type proteins were also sequenced on a HiSeq instrument at a different facility. Libraries were trimmed to remove Illumina- and library-internal adapter sequences using the FASTX toolkit (Hannon lab) and loaded into the R environment using the R package named SELEX (http://bioconductor.org/packages/release/bioc/html/SELEX.html) (Riley et al., 2014).

Computational analysis of complex configuration
Relative enrichment tables for all libraries were generated using the SELEX package. To color the individual oligomers based on the complex composition most likely explaining their enrichment, position-specific-affinity matrices were generated for HthHM-Exd-Dfd using a 12-mer seed sequence from Lib-16 (12-mer with highest enrichment), for HthFL-Exd using a 10-mer or 12-mer seed (TGATGCAG or TGAGTGCAGC), and for dimeric HthFL using a 12-mer seed (TGACAGCTGTCA; Lib-30). Each sequence from each respective library was then scored with the different PSAMs and complex composition assigned based on the PSAM achieving the highest score. To remove shifted binding sites that do not encompass the full TF footprint, only sequences with a relative affinity score > 0.01 for one of the three PSAMs were retained.

To test for preferences in complex orientation with respect to the fixed Hth site in the Lib-Hth-(F/R) libraries, overall 12-mer relative enrichment tables were generated as described above and forward or reverse-complement orientation assigned by comparing the relative enrichment of each 12-mer to that of its reverse complement. Sequences with a higher score for the forward strand (as obtained from the sequencing run) were designated as [Exd-Hox]F and sequences with a higher score for their reverse complement as [Exd-Hox]R. Average F/R ratios for Lib-16 (HthHM-Exd-Dfd) and Lib-Hth(F/R) were shown as boxplots (Figure S1C).

To account for varying offsets of the Exd-Hox binding site, 12-mer enrichment tables were generated for each offset respectively (using the SELEX function selex.affinities(…, offset = x) with x = 0 to 9) and F and R orientation assigned as described above. To test for sequence preferences within the DNA spacer connecting the Hth and Exd binding sites, 16-mer enrichments of sequences right downstream of the fixed Hth site of Lib-Hth(F/R) (offset = 0) were computed and sequences isolated that matched the top Exd-Hox binding site (ATGATTAATCAC) at position 5-16. A+T content of the variable 4bp spacer sequence was computed and compared to the relative enrichment of each 16-mer (spacer) sequence (Figure S1F).

For the comparison of k-mer based relative enrichment plots between wild-type and shape-readout mutant SELEX libraries, each sequence was assigned an F or R orientation as described above, as well as a representative complex that best explained the sequence signature (using PSAMs, see above). In addition, Exd-Hox type sequences were split based on the Y5 (C or T) or the N1 (A,C,G,T) base identity within the consensus 12-mer binding sites (NTGAYNNAYNN; Figures 4A and S3). For representation purposes, only sequences in F orientation and with a PSAM score > 0.005 were shown. Sequences that had similar scores (less than 3-fold difference) for more than one PSAM, or that did not match the respective Y5 pattern (e.g., due to a partial motif), were labeled ambiguous and colored separately (gray).

Feature-based modeling using GLM
To model the relative orientation and offset preferences for the Exd-Hox subcomplex within the HthFL-Exd-Hox ternary complex quantitatively in a unified model, each 21-bp probe sequence (including 2 bp of flanking sequence) was first scored on both strands with a PSAM obtained from the HthHM-Exd-Dfd dataset from Lib-16. Only probes for which a single binding site solely accounted for > 95% (the “confidence” value) of the probe selection were retained. A similar procedure was described in Zhang et al. (2018). Probes with identical 12-mer Exd-Hox sequences, spacer length, and assigned orientation were collapsed to one entry in the design matrix and their individual counts were added up. The collapsed R2 counts were used as dependent variables in the generalized linear model, log-transformed corresponding R1 counts were used as an offset and both log-transformed Lib-16 derived relative enrichments for the Exd-Hox subcomplex and the overall configuration, as defined by the combination of spacer length and the
orientation of Exd-Hox ([Exd-Hox]_C or [Exd-Hox]_R) were used as predictors/features in the model. The model was fit using the R function glm(..., family = poisson) based on the following model, where S_probe represents the sequence of the Exd-Hox 12-mer with a specific configuration:

$$\frac{\Delta G(S_{probe})}{RT} = \sum_{c} \beta_{c}^{config} (S_{probe}) + \beta_{c}^{ExdHox} \Delta G^{ExdHox}(S_{probe}) / RT$$

Here $\beta_{c}^{config} (S_{probe})$ is an indicator function that is implicitly dependent on the Exd-Hox binding model and takes on the value of 1 if probe sequence S corresponds to configuration c and equals 0 otherwise; $\beta_{c}^{ExdHox}$ is the corresponding coefficient that models the binding free energy contribution for configuration c; furthermore $\Delta G^{ExdHox}(S_{probe})$ represents the predicted binding free energy of the optimal 12-bp Exd-Hox binding sites within probe S; the expected value of the corresponding coefficient $\beta^{ExdHox}$ equals 1.

Oligomer-based models for sequence preferences within the spacer were obtained using the same modeling framework. The full set of confidence-filtered probes was first partitioned by offset (spacer length) and orientation. Choosing a specific offset L (e.g., spacer length $L = 4$) and orientation (e.g., Hth-spacer-[Exd-Hpx]_R), sequences identical over $L+12$ bases where first collapsed and the total R2 occurrence was used as the response variable in the model. The log-transformed Markov model predictions for the R0 initial bias of each $(L+12)$-mer was used as an offset and the spacer sequence and the relative enrichment value for each 12-mer, were used as predictors, resulting in $4^L + 1$ model predictors.

$$\frac{\Delta G(S_{probe})}{RT} = \sum_{j=0}^{4^L} \sum_{b=0}^{A} \beta_{b}^{exsolution} (S_{probe}) + \beta^{ExdHox} \Delta G^{ExdHox}(S_{probe}) / RT$$

For the mononucleotide models, the oligomers were represented by $4^L + (L+12)$ base identity indicators, reducing the parameter space:

$$\frac{\Delta G(S_{probe})}{RT} = \sum_{j=1}^{L+12} \sum_{b=A}^{T} \beta_{b}^{Isol} (S_{probe})$$

Here $I_{b} (S_{probe}) = 0, 1$ is an indicator function for the presence of base b at nucleotide position j within the probe variable region. Model comparisons were performed by computing the R² (based on a linear model) between the spacer coefficients from the oligomer model and the sum of the base coefficient covering the analogous spacer sequence in the mononucleotide model (Figure S1I).

Models with fixed N1-N2 base identity were obtained by further subsetting the probes, such that the Exd-Hox binding site would start with AT (see optimal 12-mer sequence). Fixing the first two positions allows isolating shape-dependent sequence selection within the spacer from effects due to readout occurring within the core Exd-Hox binding site. Mononucleotide models were fit for different spacer lengths as described above, while excluding the first two base positions within the Exd-Hox site from the feature set.

Affinity-shape correlation

To identify whether shape might be responsible for the observed spacer selection, we first computed the mononucleotide-model-based prediction of $\Delta G(S_{probe})/RT$ for each possible sequence of a spacer of length L followed by a 12-bp Exd-Hox site (requiring a confidence value > 90% this time). We next used a pentamer table (Zhou et al., 2015) to predict the profile of minor groove width along each sequence. Note that in all plots the first two bases within the Exd binding site (N1N2) were fixed to AT – the optimal choice – to isolate TF shape preferences within the spacer/flanks from those within the Exd-Hox partial binding site. This is necessary as shape features are computed using pentamer tables, which means that any shape readout within the spacer is conditioned on the identity of upstream bases. A change in neighboring base identity might result in a new protein conformation with a distinct shape preference. For that reason, we also extended spacer sequences 5’ of the fixed Hth binding site present in the flanks of Lib-Hth-(F/R). The resulting MGW profiles for all sequences were ranked by their $\Delta G(S_{probe})/RT$ and average MGW profiles were obtained along sets of sequences. To test for a role of MGW in selection, we first computed the average MGW profile including all spacers, setting a reference point of random or no selection. We then subsequently increased the threshold for spacers included in the analysis based on their $\Delta G(spacer)/RT$ ranking and recomputed the average MGW profile on the reduced set. Sequentially removing “bad” spacers from the pool should reveal any preference for a specific MGW profile, as it mimics the underlying, biophysical selection process. Since no meaningful flank is present for the HthHM-Exd-Hox and Exd-HthFL complexes, mononucleotide feature models were also obtained from the R2 or R1 counts of sequences with the core binding site extended by 6bp (HthHM-Exd-Hox; including the library flank) or 4bp (Exd-HthFL; limited by sequencing depth) up- or downstream (Figure 3B).

Structural interpretation

Structural representations (superimpositions) were obtained with the align function in pymol, using the DNA or one of the proteins (Figures 2C and S2E) as the template. Extended B-DNA with sequences accommodating the respective homeodomains and spacers were generated with the Nucleic Acid Builder webserver (Macke and Case, 1998).

Generation of transgenic and CRISPR-Cas9 fly lines

The full-length cDNA sequence for either the wild-type or the R2A.R5A mutant Exd (obtained by PCR from the protein-expression vectors), followed 3’ (C-terminally to the protein) by the sequence coding for the small V5 peptide, was ligated into the multiple cloning
site (MSC) of a vector with attB sites for φC31-mediated integration. The vector contained a tubulin (Tub) promoter and a poly-adenylation signal surrounding the MSC. Purified vectors were sent for injection into the attP40 site on chromosome 2L, additionally marked with w+. The resulting flies were crossed with respective balancer males or females (sp/CyO; MKRS/TM2) and transgenes were tested for their ability to rescue an exd null allele.

For Antp ChIP-seq experiments, a GFP-tag was fused in frame into the endogenous Antp locus at its N terminus (details upon request; S.F. and R.S.M., unpublished data), resulting in homozygous viable GFP-Antp flies.

Fly lines carrying endogenous Exd with a C-terminal Green Fluorescent Protein (GFP) tag were ordered from Rainbow, using their CRISPR-based protein tagging service. The final line harbors a GFP directly fused to the last coding amino acid of Exd, followed by an SV40-poly(A) signal and a DsRed Express cassette for easy screening. Progeny obtained from the initial red fluorescent screen were homozygous viable. Fly lines used for RNA-seq experiments were the result of a cross between i) female flies homozygous for both Exd-GFP (X chromosome) and a temperature-sensitive Tub-GAL80ts-UAS-deGradFP (Caussinus and Affolter, 2016) (2nd chromosome) and ii) male flies carrying either Tub-ExdWT-V5 or Tub-Exdshape-V5 transgene on the second and an enhancer-trap into the headcase locus driving Gal4 (hd-c-G4) on the third chromosome over C(2L;3R);Tb. Flies selected for RNA-seq were males of the following genotype: Exd-GFP/Y; Tub-Gal80ts-UAS-DeGrad/Tub-ExdWT or -shape-V5; hdc-G4/+.  

Immunohistochemistry
The following antibodies for immunohistochemistry were used: rabbit anti-Exd (Abu-Shaar and Mann, 1998), mouse anti-V5 (Invitrogen, R960-25), rabbit anti-GFP (Invitrogen, A-11122). Imaginal wing discs were collected from third instar larva, fixed in 4% formaldehyde for 25 minutes and stained with the antibody overnight in a 1:500 dilution. Discs were imaged at 20× magnification using confocal microscopy and processed using ImageJ software.

ChIP-seq
The following antibodies were used in ChIP-seq experiments: mouse anti-V5 (Invitrogen, R960-25), rabbit anti-GFP (Invitrogen A-11122) for Antp-GFP, guinea-pig anti-Hth (Ryoo et al., 1999), mouse anti-Antp (DDHB, C811), rabbit anti-GFP (Invitrogen, A-11122). Imaginal wing discs were collected from third instar larva, fixed in 4% formaldehyde solution for 25 minutes and stained with the antibody overnight in a 1:500 dilution. Discs were imaged at 20× magnification using confocal microscopy and processed using ImageJ software.

ChIP-seq

ATAC-seq

Wing imaginal discs of third instar larvae were dissected from a lab stock of w/y genotype in Phosphate-Buffered-Saline. Discs were washed in nuclear extraction buffer (NEB, 10mM HEPES pH 7.5, 2.5mM MgCl2, 10mM KCl) and placed in a 1mL dounce homogenizer (Wheaton) on ice. Discs were treated with 15 strokes of the loose pestle, followed by a 10-minute incubation on ice, then 20 strokes of the tight pestle. Nuclei were counted using a hemocytometer, and 50,000 nuclei were transferred to a fresh Eppendorf containing 1mL of NEB buffer +0.1% tween-20. Following a brief mixing the nuclei were immediately pelleted for 10 min at a speed of 1000xg. The pellet was re-suspended in ATAC transposition buffer as in Buenrostro et al. (2015) and tagmentation was carried out as previously described (Buenrostro et al., 2015). Amplified libraries were purified, and size-selected using double-sided ampureXP (Beckman) size selection.
**In situ Hi-C**
Wing imaginal discs of third instar larvae homozygous for both endogenous and tub > exdWT-V5 were dissected in PBS (with 0.5% Bovine Serum Albumin (BSA)). Discs were transferred to 1x Schneider’s Drosophila medium (GIBCO) and pelleted at 300 g. A single-cell suspension was generated by incubating the discs for 15 min at RT in 200 μl of Schneider’s medium containing 1 μg/ml of papain enzyme. The dissociation reaction was quenched by adding 800 μl of Schneider’s medium with 10% Fetal Bovine Serum (FBS) and pipetting up and down at least 10 times. The cell suspension was pelleted at 600 g (5 min at 4°C). Immediately after the dissociation, cells were cross-linked for 10 min (RT) in 1% methanol-free formaldehyde solution. For all subsequent steps, the protocol described in Monahan et al. (2019) was followed using the restriction enzyme DpnII and Ovation’s Ultralow System V2 for library preparation.

**RNA-seq**
Crosses to obtain flies with transgenic Exd being the dominant source of Exd were set up as described above and raised at 18°C. 24 hours before RNA isolation, larvae were shifted to 29°C. 2-4 wing discs of third instar, male, wandering, non-Tb larvae were obtained for each deGradFP RNA-seq experiment. For wild-type, larval central nervous system and wing disc RNA-seq samples, flies were raised at 25°C and 4-5 third instar wandering larvae were used per sample (3 replicates each). Discs were dissected on ice in PBS with 0.5% BSA and transferred to 350 μl of RLT buffer (QIAGEN) with 1% β-mercaptoethanol (BME). Discs were homogenized with a plastic pestle and frozen at −20°C (no more than 1 week). To each sample 100 μl PBS and 250 μl Ethanol was added, and RNA was purified using the QIAGEN RNeasy mini kit (QIAGEN 74104). RNA was next treated with DNasel (NEB) for 30 min at 37°C, followed by another column purification using QIAGEN’s RNeasy micro kit (QIAGEN 74004). RNA quality was assessed with a RNA Pico Chip (Agilent) on a Bioanalyzer and only non-degraded samples were used for subsequent library generation. RNA-seq libraries were prepared using NEB’s NEBNext Ultra II Directional RNA Library Prep Kit for Illumina Sequencing (NEB EE7760S) and following the instructions for the poly(A) mRNA magnetic Isolation Module. AMPure XP beads (Beckman Coulter) were used for DNA library size-selection. DNA library quality was assessed with a High Sensitivity DNA Chip (Agilent) on a Bioanalyzer and quantification was performed using a Qubit fluorometer. Two replicates were obtained for the Exd\textsuperscript{shape} experiments and three replicates each for the CNS and wing-disc RNA-seq samples.

**ChIP-seq Library Preparation**
ChIP-seq libraries were constructed using the NEBNext Ultra DNA Library Prep Kit for Illumina with NEBNext Multiplex Oligos (one separate index per sample) following standard instructions. For the PCR amplification, 13-15 cycles were used depending on the amount of starting material, which was generally between 3-10 ng of precipitated DNA. For the input samples no more than 10 ng of DNA was used to match input and IP samples as closely as possible. For the final size selection, AMPure xp beads (Agencourt) were used and larger (> 550bp) and smaller (< 150bp) fragments were removed by a double-sided size selection with first 0.6x volume of beads to DNA and retaining the supernatant, followed by a final concentration of 0.9x beads to DNA and retaining the DNA-bound to the beads. Quality control was done by assessing the DNA size distribution with a Bioanalyzer. ChIP-seq, ATAC-seq, RNA-seq and Hi-C libraries were diluted to 2 nM, using a Qubit to verify the final concentration, pooled and sequenced with a v2 75 or a 150 cycle high-output kit using either single-end (ChIP-seq, ATAC-seq) or paired-end (RNA-seq, HiC) settings on an Illumina NEXTSeq Series desktop sequencer at Columbia University.

**ChIP-seq and ATAC-seq data processing**
The four separate, raw fastq-files (from the four lanes of the sequencing run) were first collapsed into one file and subsequently aligned (bowtie2) (Langmead and Salzberg, 2012) to the D. melanogaster genome version dm6 (2014, GenBank accession: GCA_000001215.4). Sequencing statistics and alignment rates are reported in Table S1. Aligned sam files were next converted into bam files, sorted and cleared from duplicate reads using the samtools functions view, sort and rmdup (Li, 2011; Li et al., 2009). The sorted, unique bam files were indexed and converted into bigwig files using the bamCoverage function in the Deeptools suite with parameters -bs 1 -e 125 (Ramirez et al., 2014). For ChIP-seq, peaks were called using the MACS2 (Zhang et al., 2008) function callpeak using the input samples as control files with parameters -q dm -q 0.01 or 0.05–nomodel–extsize 125. For further downstream analysis, peak summits from the more deeply sequenced Exd\textsuperscript{WT-V5} ChIP replicate with a q-value threshold of 0.01 were used.

**Hi-C data processing**
The four separate, raw fastq-files were first collapsed into one file. For downstream data processing the Juicer Tools Version 1.76 pipeline5 was used (Durand et al., 2016). The DpnII restriction site file was generated using the Drosophila genome version dm6 and the python script provided by Juicer Tools. The highest resolution to create the .hic file was set to 5 Kb. To remove multi-mappers, only reads meeting the MAPQ > 30 cutoff were used. The number of sequenced reads and the alignment rate are reported in Table S1. For this study only intrachromosomal contacts were considered. Contacts were dumped using the contact extraction tool Straw (Durand et al., 2016) with normalization method VC (vanilla coverage) at 25 Kb and 5Kb resolution. In addition, the function “dump” from the Juicer Tools toolkit was used to extract contact matrices normalized for pairwise distance by using the observed/expected option (dump -oe -NONE). Binned Hi-C contacts were loaded into R for further data analysis.
RNA-seq data processing and analysis

The four separate, raw fastq-files (from the four lanes of the sequencing run) were first collapsed into one file and subsequently aligned with hisat2 (Kim et al., 2015) to the D. melanogaster genome version dm6 (2014, GenBank accession: GCA_000001215.4). Sequencing statistics and alignment rates are reported in Table S1. To obtain information on preferential promoter usage (across different isoforms), the RNA-seq data were also aligned to the most recent transcript assembly (ENSEMBL) using the program Salmon (Patro et al., 2017). Differential gene expression was analyzed in R using packages Rsubread (Liao et al., 2019) and DESeq2 (Love et al., 2014). Only genes with at least 50 counts in either ExdWT or Exd-shape sample were used (total of ~8500 genes). Volcano plots were generated by using a false discovery rate (FDR) of 5% for differentially expressed genes and using the DESeq2 empirical bayes shrinkage method for fold-change estimation (Love et al., 2014). For the association of contact frequency and fold change expression the same method was used.

Coverage Plots and Downstream Peak Analysis

Heatmaps for the raw IP coverage of the four ChiP-seq samples and ATAC-seq sample (Exd, Hox, ATAC-seq) were generated on the Exd peak set sorted by the ExdWT-V5/Exdshape-V5 IP-ratio using the DeepTools functions computeMatrix and plotHeatmap (parameters:--sortRegions “no”--refPointLabel--missingDataColor 1). Raw read coverage was extracted at the Exd peak summits (-q-value = 0.01) from the bigwig files for all ChiP samples. Further comparisons between ExdWT-V5 and Exdshape-V5 were based on the combined coverage of both replicates. For each Exd peak, sequences surrounding the peak summit (± 50bp) were extracted. Each peak sequence was then scanned with (i) an Exd-Antp binding model (obtained by fitting a No Read Left Behind (NRLB) model (Rastogi et al., 2018) to the Lib-16 dataset for HthHM-Exd-Antp, (ii) an Exd-Hth model (obtained by fitting a NRLB model to the Lib-16 data for HthFL-Exd), and (iii) a Hth-only model (PSAM model derived from Lib-30, using TTGACAGC as a seed). For each model view (in total there are [100-number of positions specified by the model] +1) possible binding sites in each 100bp peak sequence), the score was computed for the “+” and “-” strand respectively and only the maximum of the two was considered for each view. The cumulative peak score for each model was computed by summing up the scores across all views, with the score for any specific view v in terms of the underlying sequence Sv defined by:

\[
\text{PeakScore}_v = \exp \left[ \frac{-\Delta G(S_v)}{RT} \right]
\]

Testing for the stabilizing role of the Hth homeodomain to Exd-Hox sites was done by first considering the subset of peaks with a high confidence Exd-Hox site, a match to the consensus 12-mer NTGAYNNAYNNN (752 peaks). Next the subset of Exd-Hox peaks was split into the 30% of peaks with the strongest loss of Exdshape binding and the remaining 70% of less lost peaks. Both the cumulative Exd-Hox peak score as well as the affinity of the highest scoring Hth site (excluding the highest scoring Exd-Hox site) were compared between the two sets (t-test; 30% versus 70%). For the comparison between “high affinity” (Y5 = T) and “low affinity” (Y5 = C) sites, peaks were scanned for motif matches for NTGAY5NNAYNNN (752 peaks) and subdivided based on the identity of the Y5 position (T or C). The t-distribution was used to test for significant differences in the IP-coverage for Antp-GFP, ExdWT-V5, and Exdshape-V5 between the two affinity classes.

For de novo motif discovery using MEME-ChIP, 300 bp centered around the summits of all 852 motifless sites were used as input together with 852 control regions that were taken 1kb away from the original peak coordinates. MEME-ChIP was run in “differential enrichment mode” using the combined Drosophila datasets and default settings.

Clustering and peak to gene assignment

To cluster peaks based on their potential complex composition, 6 input features were considered: (i-iii) raw IP enrichment for ExdWT-V5, Exdshape-V5, AntpGFP, and (iv-vi) peak scores for Exd-Antp, Exd-Hth (both NRLB models), and Hth-only (PSAM model). The resulting peak by feature table, was then transformed into standard scores (Z-scores) prior to cluster analysis. To cluster peaks on the 6 input features, the R package ‘flexclust’ was used with function cclust (method = “neuralgas,” k = 8). Eight clusters were chosen to allow for capturing of all possible complexes in addition to affinity differences and potentially unknown modes or accessibility driven, non-specific binding. Complex composition was assigned based on considering the average feature score for each cluster, as well as the degree of signal loss and peak accessibility (ATAC-seq; not included in the clustering).

Hi-C data analysis

To visualize Hi-C contacts among Exd peak sets, all 5Kb genomic bins containing a peak were extracted, and analyzed in two distinct ways: (i) a 5Kb bin was assigned to each Exd peak, resulting in duplicate Hi-C bins whenever multiple peaks fell within the same bin, yet maintaining one interaction per peak (Figure 6E); (ii) only unique Hi-C bins were retained, regardless of how many Exd peaks were associated with them (Figure S6A). In the same manner, random, size matched controls were generated by sub-sampling from the entire set of ATAC-seq peaks (~20,000). To compute p values, at least 50 such random size-matched samples were generated. Average Hi-C contact frequencies were obtained by simply taking the mean across all 5Kb binned
Hi-C contacts for a particular peak set. In addition, normalized Hi-C contact maps were generated using the observed over expected method reported by Rao et al. (2014) (Figure S6A, insets). To generate an average Exd-shape binding loss for motifless Exd binding sites based on their connectivity with motif-dependent Exd binding sites, three approaches were used: i) the Exd-shape binding loss at the site with the highest interaction frequency with each specific motifless site was used; ii) the average Exd-shape binding loss was computed from all sites that had a Vanila Coverage corrected Hi-C interaction frequency of at least 10 (including contacts below this threshold results in continuously decreasing correlations). Averaging of Exd-shape IP signal loss was done by taking the log2 value of the interaction frequency between motif-dependent and motifless sites as a weight; iii) the average Exd-shape binding loss was computed from random associations of motifless and motif-dependent sites on the same chromosome. In this last approach, the number of motif-dependent peaks for each motifless site was kept identical to that of approach ii). Correlations between the Exd-shape IP signal loss at a motifless sites and those computed under i), ii), or iii) were calculated with the R function cor.test using method = “spearman.” The computation of p values for correlations under approach i) and ii) compared to those under iii) was done by repeating step iii) 100 times to generate a distribution of expected random correlations.

To assign peaks to a promoter the vanilla coverage (VC) normalized contact frequency for each peak across all promoters in the RNA-seq dataset was computed. To simplify the analysis, only one promoter per gene (in case of multiple isoforms) was considered; the choice of promoter is based on whether a specific isoform was itself differentially expressed or (if not) whichever isoform had highest expression levels. The highest scoring peak-promoter interactions were then taken as the most likely target gene for each peak. To determine whether an individual promoter is significantly contacted by any of the five Exd peak types, the cumulative peak-promoter contact frequency within ± 50 Kb of the promoter was extracted from the Hi-C data. Pearson correlation was next computed between the log2-gene-expression-fold change and the cumulative contact frequency. For visualization, promoters were split into equally sized bins (in 5 percent increments) based on the cumulative contact frequency (Figure 6D).

Gene Ontology analysis
Gene Ontology (GO) analysis was performed using the R package goseq (Young et al., 2010). Tests were performed using the set of promoters that were both upregulated (5% FDR) and had an associated Exd peak, based on the maximum contact peak-to-promoter method described above. To test for contributions of individual complexes, only those promoters associated with a specific complex were used. Only GO categories with less than 1500 genes that scored significant in at least one of the complex-specific or all Exd gene sets (after correcting for multiple hypothesis testing) were considered for visualization. To test whether the enriched GO categories overlap with central nervous system (CNS)- or wing-specific functions, GO analysis was also performed on the intersection between upregulated genes in Exd-shape and i) the geneset upregulated in the CNS or ii) in wing discs from a transcriptome comparison of wild-type tissues (for genotype information see above). If a GO category scored significant in one of the two latter genesets it was colored as CNS- or wing-specific respectively.

QUANTIFICATION AND STATISTICAL ANALYSIS

Image quantification competition assays
Raw images were quantified using ImageJ and the fraction bound (normalized to no competitor lane) plotted against the log protein concentration. IC50 values with standard deviations are shown in Figures S1F and S1E and represent the protein concentration (in nM) at which the initial bound fraction is reduced in half.

Configurational free energy estimates
The Hth-Exd-Dfd configurational free energy estimates displayed in Figure 2A represent the coefficients as obtained from the GLM fit. P values for energy estimate as obtained by the GLM fit were significant defined by a p.val < 0.05.

Statistical analysis of in vivo results
Correlation estimates and p values are provided in each figure. For Figures S4C and S4D, the statistical test was based on a standard Student’s t test. For Figure S5B a Wilcox test was performed, with p values indicated by $p_{\text{wc}}$. For RNA-seq data the threshold for significantly up- or downregulated genes was set at a 5% False Discovery Rate. The null distribution for the correlation of ExdWT/Exd-shape IP signal ratios between motifless and motif-dependent Exd peaks was generated as follows: For each motifless peak one or more motif-dependent peaks (matched to the true number of interacting peaks) located on the same chromosome were randomly assigned and the correlation for ExdWT/Exd-shape IP signal loss across all pairs was computed. In total, 100 such sampled correlations were generated. The distribution of randomly sampled correlations was then used to determine the probability of
observing the true correlation between motifless and motif-dependent pairs (using the Hi-C contacts; VC normalized threshold set to either i) the highest contact, or ii) all contacts with Hi-C contacts > 10; see Figure S6C).

**DATA AND CODE AVAILABILITY**

The accession number for the raw sequencing data of both in vitro (SELEX-seq) and in vivo (ChIP-seq, ATAC-seq, RNA-seq and Hi-C) experiments as well as the Exd peak set reported in this paper is GEO: GSE125604.
Supplemental Information

Context-Dependent Gene Regulation by Homeodomain Transcription Factor Complexes Revealed by Shape-Readout Deficient Proteins

Judith F. Kribelbauer, Ryan E. Loker, Siqian Feng, Chaitanya Rastogi, Namiko Abe, H. Tomas Rube, Harmen J. Bussemaker, and Richard S. Mann
Figure S1. Binding Preferences and Model Comparison. (related to Figure 1)
(A) Comparison of Exd-Hox binding preferences in the presence or absence of a Hth site. Normalized relative 12-mer enrichments for the ternary HthFL-Exd-Hox (Lib-Hth-R) are compared to those for HthHM-Exd-Hox (Lib-16). 12-mer enrichments are colored based on the most likely Exd-Hox binding orientation with respect to the upstream fixed library flank: [Exd-Hox]_F with a higher enrichment score for the forward 12-mer (blue); and [Exd-Hox]_R with a higher score for the reverse orientation (red). The fixed Hth site introduces a preference for the [Exd-Hox]_F orientation. (B) 12-mer enrichments are compared between Lib-30 with trimeric HthFL-Exd-Dfd and Lib-16 with HthHM-Exd-Dfd bound. Main binding modes are recognized: (i) Hth-dimer sequences (purple), (ii) canonical Exd-Hth sites (dark blue) and (iii) Exd-Hox sites (green; shade implies the orientation of the binding site with respect to the library sequencing flanks). (C) Effect size of orientation preferences introduced by the fixed Hth site in either Lib-Hth-F or Lib-Hth-R compared to Lib-16 HthHM-Exd-Dfd. Binding to the forward or reverse [Exd-Hox]_(F/R) motif occurs in equal ratios in the symmetric Lib-16 (HthHM-Exd-Hox), whereas both Hth-F and Hth-R libraries have relative enrichment ratios of [Exd-Hox]_F over [Exd-Hox]_R greater than one (average of ~3 for Lib-Hth-R, pink; of ~2 for Lib-Hth-F, purple). (D) Relative 12-mer enrichments by offset to fixed Hth site in Lib-HthR. Preference for [Exd-Hox]_F varies with spacer length. (E) Competition assay validating the spacer preference of the trimeric HthFL-Exd-Hox complex: three different spacer sequences – 0, 3, and 7bp – in between the Hth and Exd-Hox binding sites (CTGTCA-(N)_L-ATGATTAATGAC) were used to compete with a radiolabeled Hth-Exd-Hox probe (CTGTCA-AAA-ATGATTAATGAC). Agreeing with the model (Figure 2A), spacers of 3 and 7 bp competed out the labeled probe at lower concentrations compared to a suboptimal spacer of 0 bp (IC50 values of 17.5 ± 3.7; 28.5 ± 3.2, and 192.5 ± 28 nM for spacers of 7, 3 and 0 bp respectively). (F) Sequence preferences of the DNA spacer between Hth and Exd-Hox. Relative enrichment for 16mers with a fixed Exd-Hox site at positions 5-16 are shown and colored based on A/T content. (G) Schematic for detecting shape-readout of DNA spacer sequence: For a specific spacer length, mononucleotide models are fit to the SELEX round 2 count data and the affinity score and the minor groove width (MGW) is computed for each sequence. Intrinsic, average DNA MGW profiles are correlated with TF binding selectivity to test for shape readout. (H) Spacer affinity scores were generated by either fitting a mono-nucleotide model (blue) or a k-mer model (orange) to the round-2 SELEX-seq count data. Either sum of coefficients (mono-nucleotide model), or the individual spacer coefficients were used to compute spacer affinity scores. (I) The 4-bp spacer ∆∆G/RT coefficients were compared for either the mono-nucleotide model (blue) or the k-mer model (orange) (R^2= 0.81).
Figure S2. Binding behavior of Exd and Hth mutant proteins. (related to Figure 2 and 3)
for the HthHM-Exd-Hox complex. Wild type Exd and the hydrogen-bond disrupting ExdN51A proteins are used for comparison: Lane 1: DNA only; lane 2: Dfd only, lane 3: HthHM-ExdWT-Dfd, lane 4-6: HthHM-ExdR3A,R6A-Dfd, lane 7-8: HthHM-ExdN51A-Dfd. (C) Electromobility shift assay for combinations of Exd N-terminal arginine mutants with either HthHM or HthFL isoform or with Hthshape mutant protein. Lane 1: DNA only; lane 2: Dfd only, lane 3: HthHM-Exd-Dfd, lane 4-5: HthHM-ExdR3A,R5A-Dfd, lane 6-7: HthHM-ExdR5A,R6A-Dfd, lane 8: HthFL-Exd-Dfd; lane 9-10: HthFL-ExdR3A,R5A-Dfd; lane 11-12: HthFL-ExdR5A,R6A-Dfd, lane 13-14: HthK3A,K4A,R5A-ExdR2A,R5A-Dfd. (D) Electromobility shift assay for Hthshape (HthK3A,K4A,R5A) and Exdshape (ExdR2A,R5A) mutant proteins as used for the mutant Lib-Hth-(F/R) SELEX experiments. Lane 1: DNA only; lanes 2 and 7: Dfd-only; lane 3-5: Hthshape-Exd-Dfd; lane 8-10: HthFL-Exdshape-Dfd. (E) Visualizing binding mode differences by structural superimposition of either Exd-Hox (PDB-ID: 2R5Y; Exd=green, Hox=blue) or Exd and MEIS1 (PDB-ID: 4XRM; pink) onto B-DNA. In Exd-Hox the YPWM motif directly interacts with Exd’s HD, potentially intensifying Exd’s shape readout through cooperative binding behavior. Hth uses its HM-domain that is connected via a flexible linker to Exd’s PBC domain (indicated here as colored circles) to connect to Exd. It is likely that the binding is DNA mediated thus allowing Exd to bind in its native, monomeric mode.

**Figure S3. Exd\textsuperscript{shape} differentiates complex compositions.** (related to Figure 4)  
(A-C) Comparison of 12-mer relative sequence enrichments between Hth\textsuperscript{FL}-Exd-Hox and Hth\textsuperscript{FL}-Exd\textsuperscript{shape}-Hox (Lib-Hth-R) continued from Figure 4A. (B) and (C) show blow-ups of Y5=C (top) or Y5=T (bottom) 12-mer sequences. Each individual box shows subsequences that vary in the N1 base identity (N1=A,C,G, or T) and the degree to which they are lost in Exd\textsuperscript{shape} (lines represent linear fit). (D) Comparison of 12-mer relative sequence enrichments between Hth\textsuperscript{FL}-Exd-Hox and Hth\textsuperscript{FL}-Exd\textsuperscript{shape}-Hox (Lib-Hth-F). 12-mers are colored by the PSAM sequence score most likely explaining their enrichment: Hth-dimers (purple), canonical Exd-Hth\textsuperscript{FL} binding (dark blue), Hth\textsuperscript{FL}-Exd-Hox bound to the lower affinity sites (Y5=C: NTGACNNAYNN; coral red), and Hth\textsuperscript{FL}-Exd-Hox bound to the high affinity sites (Y5=T: NTGATNNAYNN; green). (E) and (F) Blow-up of Y5=C (top) or Y5=T (bottom) 12-mer sequences from plot (D). Each individual box shows subsequences that vary in the N1 base identity (N1=A,C,G, or T) and the degree to which they are lost in Exd\textsuperscript{shape} (lines represent linear fit). (G) Comparison of 12-mer relative sequence enrichments between Hth\textsuperscript{FL}-Exd and Hth\textsuperscript{FL}-Exd\textsuperscript{shape} (Lib-16). 12-mers are colored by the PSAM sequence score most likely explaining their enrichment: Hth-dimers (purple), canonical Exd-Hth\textsuperscript{FL} binding (dark blue). (H) Blow-up of 12-mer sequences from plot (G). Each individual box shows subsequences that vary in the N1 base identity (N1=A,C,G, or T) and the degree to which they are lost in Exd\textsuperscript{shape} (lines represent linear fit). (I) Proposed mechanisms for the sequence-dependent, differential binding loss of Hth\textsuperscript{FL}-Exd\textsuperscript{shape} -Hox. Average MGW profiles are shown for the top 10 highest scoring sequences when the N1 base is either fixed to A (light green) or C (dark green) before fitting the binding model. N1=A type sequences have an optimal, narrow MGW along the entire N-terminal end of Exd, thus more likely to be affected by a mutation removing shape readout, whereas N1=C type sequences have a much wider MG thus their binding mode is less impacted. (J) As in (I) but for position Y5 (coral red: Y5=C and green Y5=T). Widening of the MGW at positions N3-6 and the resulting shift in readout preferences is likely to explain the differences in Exd\textsuperscript{shape} binding to the two types of sequences.
Figure S4. Using Exd\textsuperscript{shape} to probe complex composition and binding mechanisms in vivo. (related to Figure 4 and 5)
(A) Transgenes carrying either Exd<sup>WT</sup> or Exd<sup>shape</sup> tagged with V5 are inserted into the attp40 landing site on chromosome II. Removing endogenous Exd transcripts is rescued by Exd<sup>WT-V5</sup> (9 males of 68 progeny, expected 8.5) but not Exd<sup>shape-V5</sup> (0 males of 89 progeny, expected 11, \( p = 0.004 \)).

(B) Anti-Exd (green) and anti-V5 (cyan) stain of homozygous Exd<sup>WT</sup> or Exd<sup>shape-V5</sup>-tagged 3<sup>rd</sup> instar imaginal wing discs (in the background of endogenous Exd). V5 signal follows total Exd stain and is nuclear in both genotypes. Scale bars indicate 100 \( \mu \)m.

(C) Hth<sup>FL</sup> binding stabilizes binding loss of Exd-Hox dimers: The 752 peaks containing a match to the consensus Exd-Hox site (TGAYNNAY) were split according to Exd<sup>shape</sup> binding loss (ratio Exd<sup>WT</sup>/Exd<sup>shape</sup>; 30:70 - red:grey) and the peak sequences (100 bp around summit) were scored with either Exd-Antp (turquoise) or Hth (pink) motif models. 30:70 peak sets were tested for differences in Exd-Antp BS peak score and the presence of a secondary Hth motif.

(D) The 752 peaks with a match to an Exd-Hox TGAYNNAY site were split into two groups \( Y_5=C \) (low affinity; coral red) and \( Y_5=T \) (high affinity; green), and the \textit{in vivo} sequence selectivity for Antp, Exd<sup>WT</sup> and Exd<sup>shape</sup> is compared between the two groups. Exd<sup>shape</sup> prefers the low affinity \( Y_5=C \) over the high affinity \( Y_5=T \) sites.

(E) Scatterplot of Exd<sup>shape-V5</sup> IP enrichment against Hox (Antp-GFP) IP enrichment for all \( \sim 3700 \) Exd<sup>WT-V5</sup> peak summits. Coloring is based on peak clustering using i) the full feature set (three IP signals (Exd<sup>WT-V5</sup>, Exd<sup>shape-V5</sup>, Antp-GFP) and three binding site scores (Exd-Antp, Hth-only, Exd-Hth; \textit{in vitro} binding models); ii) 5 out of 6 features, leaving out Exd<sup>shape-V5</sup> (middle panel); iii) 5 out of 6 features, leaving out Antp IP signal (right panel). Only the full model correctly differentiates the “trimeric” cluster that shows stabilized Exd<sup>shape</sup> signal at high Antp IP signal (purple). Both reduced feature sets produce impure clustering; with leaving out Exd<sup>shape-V5</sup> resulting in blending of “Exd-Hox-only” and “Trimer” sites and leaving out Antp in blending of “Exd-Hth/Hth-only” and “Trimer” sites (see dashed lines and arrows).
Figure S5. **Exd**^{shape} as a tool to study complex-specific function in vivo. (related to Figure 6)
(A) Testing the deGradFP system: Images show a confocal plane of third instar imaginal wing discs, with larva raised at 18°C and shifted to 29°C 24h prior to dissection. Three different genotypes are shown: male wing disc containing one copy of Exd\textsuperscript{GFP} on the X chromosome and the Gal80 controlled deGradFP System on the second chromosome (top); female wing disc containing one Exd\textsuperscript{GFP} and one copy of endogenous Exd on the X chromosomes, the Gal80-deGradFP system and the transgenic Exd\textsuperscript{shape-V5} on the 2\textsuperscript{nd} chromosome, as well as the headcase-Gal4 driver (hd-Gal4) on the third chromosome (middle); as middle, except male disc with the endogenous Exd copy absent (bottom). In the absence of hd-Gal4, the deGradFP system is not active and Exd\textsuperscript{GFP} is nuclear (top). Upon activation of the deGradFP system the nuclear Exd\textsuperscript{GFP} is greatly reduced and Exd\textsuperscript{shape-V5} competes with endogenous Exd for nuclear localization (middle). Upon removal of endogenous Exd (by only considering male flies), and continuing to remove Exd\textsuperscript{GFP}, transgenic Exd\textsuperscript{shape-V5} is the only source of Exd protein and nuclear levels increase. Scale bars indicate 100 μm. (B) Promoters of up, but not downregulated genes in Exd\textsuperscript{shape} vs Exd\textsuperscript{WT} display a significantly higher Hi-C contact frequency (Wilcox test (wc)) for each of the five major peak classifications – Exd-Hox, Exd-Hth, Hth-only, motifless (“no-motif”), and Trimer binding sites – compared to promoters whose transcripts are not differentially expressed (non-DEG; FDR threshold set to 5%).
Figure S6. Exd binding sites physically interact. (related to Figure 5 and 6)
(A) Hi-C contact maps of wild-type (incl. tub>exd<sup>WT</sup>-V5 transgene) third instar larval wing discs isolating either the set of Exd peaks (left) or a size-matched random set of ATAC-seq peaks (right). Clusters of sites corresponding to distinct genomic contact domain structures are seen for the Exd peakset, but not for a size-matched random sample of accessible genomic regions (p-value = 2.6*10<sup>-32</sup>). The insets show the logarithm base two of the observed/expected Hi-C count ratio, computed following the method of (Rao et al., 2014), for the same peak sets. Only interactions between unique genomic bins are shown. In the left panel, whenever a genomic bin contains more than one Exd peak, one of these is chosen to represent the "bin-type" color shown along the margin of the matrix. (B) The degree of IP signal loss at motifless binding sites in response to Exd<sup>shape</sup> mutation is variable, which might be caused by 3D contacts with motif-dependent Exd binding sites. Solid dark blue double arrows indicate potential contacts between motifless and motif-containing sites; dashed grey arrows reflect the overall connectivity among Exd peaks. (C) Exd<sup>shape</sup> binding loss at motifless Exd peaks may be inherited through direct crosslinking to motif-dependent Exd binding sites. Each plot shows the motifless peak Exd<sup>WT</sup>/Exd<sup>shape</sup> IP ratio on the y-axis and the Hi-C weighted Exd<sup>WT</sup>/Exd<sup>shape</sup> IP ratio at motif-dependent sites that are associated with motifless sites on the x-axis. Three different approaches are shown to compute the motif-dependent signal loss associated with each motifless peak: (i) motif-dependent peaks on the same chromosome were randomly sampled using uniform weighting (the number of sampled peaks considered per motifless site is matched to the threshold used in (iii) see STAR Methods; grey); (ii) only the motif-dependent peak that has the highest Hi-C contact for each motifless peak was considered (orange); or (iii) all motif-dependent peaks that have a Hi-C contact >10 (vanilla coverage normalized) were included using the log10 Hi-C contacts as weights (blue). Lines represent linear fits. Spearman correlation estimates and p-values are shown above plot. (D) Spearman correlations for Exd<sup>WT</sup>/Exd<sup>shape</sup> IP ratio between motifless and motif-dependent peaks using either approach ii) (orange) or iii) (blue) described in (C) are compared to the distribution of 100 correlations generated using approach i) in (C). The probability of obtaining the observed correlations given the distribution of random peak associations are indicated above the graph.
